Search for the Higgs boson in $H \rightarrow WW^* \rightarrow ee$ decays with 0.63 $fb^{-1}$ at D0 in Run IIb

The D0 Collaboration

(Dated: September 29, 2007)

A search for the Higgs boson is presented in $H \rightarrow WW^* \rightarrow ee$ decays in $p\bar{p}$ collisions at a center-of-mass energy of $\sqrt{s} = 1.96$ TeV. Final states containing two electrons have been considered. The data, corresponding to an integrated luminosity of about $\sim 630 \, pb^{-1}$, has been collected from June 2006 to July 2007 using the Run IIb D0 detector. No significant excess above the Standard Model background has been observed, and limits on the cross section for $m_H = 120, 140, 160, 180$ and 200 GeV have been set.

Preliminary Results for P5 Meeting
I. INTRODUCTION

In this note a search for the Higgs boson decaying into the $WW^*$ final state with the D0 detector at the Tevatron collider at $\sqrt{s} = 1.96$ TeV at Fermilab is presented. Leptonic decay modes $H \to WW^* \to e\ell$ are considered, leading to final states with two electrons and missing transverse momentum. The $H \to WW^* \to e\ell^*$ decay mode provides the largest sensitivity for the Standard Model Higgs boson search at the Tevatron with a mass of $m_H \sim 160$ GeV [1–3]. Additionally the Higgs boson masses $m_H \sim 120, 140, 160$ and 200 GeV have been analyzed. The present analysis taking advantage of the ee final state is complementary to the $H \to WW^* \to e\ell^*$ analysis presented in [4] When combined with searches exploiting the WH and ZH associated production, this decay mode increases the sensitivity for Higgs boson searches.

II. DATA AND MC SAMPLES

The data sample used in this analysis has been collected between June 2006 and April 2007 by the D0 detector at the Fermilab Tevatron Collider. The NNLO $Z/\gamma^* \to ee$ cross section has been scaled to the data in the mass region $80$ GeV < $M_{ee}$ < $110$ GeV. The events are selected using various single and di-electron triggers. Applying this normalization leads to a total luminosity $\times$ trigger efficiency of $\sim 630 \, pb^{-1}$. The total luminosity recorded during RunII is about $1700 \, pb^{-1}$ from which this analysis covers the most recent run period. DATA to Monte Carlo(MC) correction factors have been applied to MC before normalization to $Z/\gamma^* \to ee$. The systematic uncertainties on the normalization factor include the $Z/\gamma^* \to ll$ cross section, the PDF uncertainty and the statistical uncertainty on the data/Monte Carlo normalization factor. As the MC is normalized to data, luminosity blocks marked as ”bad” by the luminosity system are retained.

Signal and Standard Model background processes have been generated with the Pythia 6.319 [5] Monte Carlo (MC) generator using the CTEQ6L1 parton distribution functions and subsequent use of Geant which provides a detailed simulation of the detector geometry. MC events are then processed further with the same reconstruction software as used for data. All background processes, apart from QCD multijet production, are normalized using cross sections calculated at next-to-leading order (NLO) or next-to-next-to-leading order (NNLO) based on the parton distribution functions. The signal cross sections have been calculated at NNLO, using HDECAY [6] The expected signal for all Higgs masses is given in Table. III. The background contribution from QCD multijet production where jets are misidentified as leptons is estimated from the data itself by using like-sign ee events which were selected by inverting lepton identification and calorimeter isolation criteria. The samples are normalized to the data as function of $p_T^e$ at an early stage of the selection in a region of phase space dominated by multijet production.

The $Z/\gamma \to ll$ cross section is calculated with CTEQ6L1 PDFs as $\sigma(Z/\gamma \to ll) = \sigma_{LO} \times K_{QCD}(Q^2)$, with the LO cross section calculated by Pythia LO PDF and the $K_{QCD}$ at NNLO with NLO PDF, calculated according to [7, 8]. The $W \to ev$ cross section is calculated with NNLO corrections and PDFs. The $\ell\ell$ cross section is calculated at NNLO in [9] and the WW, ZZ and WZ cross sections are calculated with MCFM v3.4.5 CTEQ5L for LO and CTEQ5M (for NLO. The uncertainties due to the PDF uncertainty is calculated in [8].

III. EVENT SELECTION

Electrons are identified by using calorimeter and tracking information. Electromagnetic showers are identified in the calorimeter, these showers are chosen by comparing the longitudinal and transverse shower profiles to those of simulated electrons. The showers must be isolated, deposit most of their energy in the electromagnetic part of the calorimeter and pass a likelihood criterion that includes a spatial track match and, in the central detector region, an $E/p$ requirement, where $E$ is the energy of the calorimeter cluster and $p$ is the momentum of the track. Both electrons must stem from the primary vertex and be reconstructed within a detector pseudorapidity $|\eta| < 3.0$. The transverse momentum measurement of the electrons is based on calorimeter cell energy information. The decay of the two $W$ bosons results in three different final states $e^+e^- + X$ (ee channel), $e^\mu^-\mu^+ + X$ (e$\mu$ channel) and $\mu^+\mu^- + X$ (e$\mu$ channel), each of which consist of two oppositely charged isolated high transverse momentum leptons and large missing transverse energy $E_T$ due to escaping neutrinos. The event kinematics change significantly as function of the Higgs mass. The mass dependent selection procedure is summarized in Table I. It will be justified and described more detailed in the following.

The signal is characterized by two leptons, missing transverse momentum and little jet activity. The selection for the ee channel as presented in this analysis requires two oppositely charged leptons with $p_T > 20$ GeV for the leading electron and $p_T > 15$ GeV for the trailing electron. Additionally the di-lepton mass is required to exceed 15 GeV. Figure 1a shows the invariant dilepton mass distribution in data, background and signal at this stage of the
selection. This stage is referred to as preselection stage. Most of the $Z \rightarrow \ell \ell$ events are rejected by requiring an upper limit for the invariant dielectron mass which is listed for the various Higgs masses in Table I. QCD background is mainly rejected by a selection requirement on the missing transverse Energy $\not{E}_T$ (see Figure 1d) and the scaled missing transverse energy $\not{E}_T^{\text{Scaled}}$, which is the $\not{E}_T$ divided by the $\not{E}_T$ resolution (Figure 2a). This quantity is particularly sensitive to events where the missing energy could be a result of mismeasurements of jet energies in the transverse plane.

$$\not{E}_T^{\text{Scaled}} = \frac{\not{E}_T}{\sqrt{\sum_{\text{jets}} \sigma_{E_T}^2 || \not{E}_T ||}}$$

A selection requirement on the minimal transverse mass, $M_T^{\text{min}}$, between one of the leptons and $\not{E}_T$ reduces further the various background processes. $M_T^{\text{min}}$ at preselection can be found in Figure 2b. The transverse mass is defined as follows:

$$M_T = \sqrt{2 \cdot \not{E}_T \cdot p_T^1 \cdot (1 - \cos(\Delta \phi))}$$

Remaining $Z/\gamma^* \rightarrow \ell \ell$ events are rejected by requiring the sum of the momentum of $p_T^1 + p_T^2 + \not{E}_T$ to be within a certain mass range as listed in Table I. The $\sum p_T$ distribution on preselection level can be found in Figure 2c. The $t\bar{t}$ contribution is reduced by requiring $H_T$, the scalar sum of the transverse momenta of all jets in the event, to be lower than 100 GeV. $H_T$ is displayed in Figure 2d at preselection.

After applying cuts 1-6 the remaining background is dominated by electroweak $WW$ and $W + jets/\gamma$ production. At this stage of the selection a Neural Network (NN) is used. The resulting NN output distribution is used for the limit setting procedure. Neural networks are a multivariate technique commonly used in high energy physics. They have been applied in RunI and RunII analysis and are used for $b$-tagging and object identification techniques ([10], [11]). Neural networks are parameterized nonlinear functions for regression or classification modeling. Inputs to a network are variables that show discrimination between signal and background. Every network used in this analysis consists of three layers of nodes, an input layer, a hidden layer and an output layer. A sigmoid function from the sum of the weighted input variables is calculated at each hidden node. The linear sum of these sigmoid functions appears at the output node. A neural network is trained with samples of simulated signal and background events. During the training process, weights are adjusted at each such that the signal is moved towards one and the background towards zero. The training of the NN has been repeated for each Higgs mass point with $WW$ MC events as background sample and the corresponding Higgs sample as signal input. About 1/3 of the available MC statistics has been used for training purpose. A list of variables sensitive to background and signal has been derived based on the separation power of the various distributions. Those variables can be divided into three classes, object kinematics, event kinematics and angular variables. A detailed list of these variables used for the NN variables can be found in Table II.

These Neural Networks are constructed for each Higgs boson mass point. The NN output for $m_H = 160$ GeV is displayed in Fig. 3.
FIG. 1: Distribution of (a) the invariant dilepton mass at preselection level (b) the leading electron $p_T$ at preselection level (b) the next-to-leading electron $p_T$ at preselection level (d) the missing transverse energy, $E_T$, at preselection level for data (points with error bars), background simulation (histograms, complemented with the QCD expectation) and signal expectation for $m_H = 160$ GeV (empty histogram). The signal contributions for $H \rightarrow WW \rightarrow ee$ are given by the solid line.

IV. SYSTEMATIC UNCERTAINTIES

The estimates for expected numbers of background and signal events depend on numerous measurements that each introduce a systematic uncertainty, lepton identification, trigger efficiencies and reconstruction efficiencies (4%), trigger turn on (4%-7%), jet energy scale calibration in signal (< 1%) and background events (1%), lepton momentum calibration (1%), Parton Distribution Function (PDF) uncertainties (< 4%) and modeling of multijet background (30%). The systematic error on the luminosity is mainly a combination of the PDF uncertainty, uncertainty for the NNLO Z cross section (4%) and data/MC normalization factors (2%). For the estimate of the background remaining after all cuts, the systematic uncertainties are small compared to the statistical uncertainties due to limited MC statistics.

V. RESULTS

Numbers of observed candidates and background events expected after application of the successive selections for $m_H = 120, 140, 160, 180$ and $200$ GeV are listed in Tab. III. The total background expectation is dominated by $W + jets/\gamma$ and di-boson events. The number of signal events are in the range of 0.07-0.46 events in the final selection.
FIG. 2: Distribution of (a) the scaled $E_T$ at preselection level (b) the minimal transversal mass $M_{T\text{min}}$ at preselection level (b) the sum of the lepton momentum and $E_T \sum p_T$, at preselection level (d) the scalar sum of the four leading jet energies, $H_T$ for data (points with error bars), background simulation (histograms, complemented with the QCD expectation) and signal expectation for $m_H = 160$ GeV (empty histogram). The signal contributions for $H \to WW \to ee$ are given by the solid line.

TABLE III: Number of candidate events observed, expected signal and expected background events at different stages of the selection for $m_H = 120, 140, 160, 180$ and $m_H = 200$ GeV. Errors are statistical only.
Since after all selection requirements the remaining candidate events are consistent with a background observation, limits on the production cross section times branching ratio $\sigma \times BR(H \rightarrow WW^*)$ are derived following the method described in Ref. [12]. This is done by using the $CL_s$ method with a log-likelihood ratio (LLR) test statistic. This method incorporates systematic uncertainties. Systematics are treated as uncertainties on the expected numbers of signal and background events, not the outcomes of the limit calculations. This approach ensures the uncertainties and their correlations are propagated to the outcome with their proper weights. The $CL_s$ approach uses binned final-variable distributions rather than a single-bin (fully integrated) value.

Table IV presents the individual observed upper limits on the cross section times branching ratio for the $e^\pm e^\mp$ decay channel and Higgs boson masses $m_H = 120, 140, 160, 180, 200$ GeV. Table V presents the expected limits for the individual channels.

VI. CONCLUSIONS

A search has been performed for the $H \rightarrow WW \rightarrow \ell\ell$ decay signature of the Standard Model Higgs boson in leptonic channels with two electrons, using data corresponding to an integrated luminosity of 630 pb$^{-1}$. No evidence for the Higgs particle is observed and upper limits using this channel on the product of cross section times branching ratio are set. Combined with existing $H \rightarrow WW \rightarrow \ell\ell$ analysis previous limits can be improved.
